Recall that $f_r(y|x) = \frac{\Pr(R = 1|y, x, S = 1) \Pr(S = 1|y, x)}{\Pr(R = 1|x, S = 1) \Pr(S = 1|x)} \cdot f(y|x)$

which implies $p_i \propto \frac{p_i^{(r)}}{\pi_i \rho_i}$.

If $E(z) = \sum_i p_i z_i = \bar{z}$ is known, $\sum_i p_i (z_i - \bar{z}) = 0$, leading to

$$\sum_i \frac{p_i^{(r)}}{\pi_i \rho_i} (z_i - \bar{z}) = 0$$

and we get our first set of estimating equations

$$\sum_i \frac{p_i^{(r)}}{\pi_i \rho(y_i, x_i; \gamma)} (z_i - \bar{z}) = 0$$

The response rate provides additional information.

Let

$$\xi_i = \pi_i \rho_i = \Pr(S_i = R_i = 1)$$

E_ξ = expectation w.r.t. combined sampling & response

$$E_\xi(r) = \sum_{j \in U} \tau_j \rho_j = N \sum_{i \in \mathcal{R}} p_i \tau_i \rho_i = N \sum_{i \in \mathcal{R}} p_i \xi_i = N \bar{\xi}_u$$

Thus,

$$r \approx N \bar{\xi}_u \quad \implies \quad r = N \bar{\xi}_u$$

With some algebra

$$\sum_{i \in \mathcal{R}} p_i^{(r)} (1 - r/(N \xi_i)) = 0$$

Which is equivalent to

$$\sum_{i \in \mathcal{R}} p_i^{(r)} \tau_i^{-1} \rho_i^{-1} = N/r$$

Once we have estimates $\hat{\gamma}$, we solve the maximization problem

$$\hat{\mathbf{q}} = \arg \max \{ \Pi(\mathbf{q}) : A(\hat{\gamma})\mathbf{q} = 0 \quad \& \quad \mathbf{q} \in \Omega \}$$

Recall that $p_i \propto \frac{p_i^{(r)}}{\pi_i \rho_i} = \frac{q_i}{\pi_i \rho_i}$, so we get $\hat{p}_1, \dots, \hat{p}_r$.

In fact, once estimates \hat{p}_i are obtained, and thus an estimate \hat{F} of the population distribution is available, non-parametric estimation of $f_p(y|x)$ can be made, for example using smooth polynomial spline.

Example: $y = \eta + \varepsilon$

where

$\eta = 0.2 + 0.03x + 0.4x^2$, restricted to $[-0.1, 0.9]$

and $\varepsilon \stackrel{\text{iid}}{\sim} N(0, 0.25)$

i.e.

$$y = \max(\min(0.2 + 0.03x + 0.4x^2, 0.9), -0.1) + \varepsilon$$

Hosmer and Lemeshow (1980, 2000): test statistic for the case of logistic regression.

Sample partitioned into G groups of approximately equal size, based on the predicted probability of 'success.' Test statistic:

$$\hat{C} = \sum_{k=1}^G \frac{(o_k - n_k \bar{\mu}_k)^2}{n_k \bar{\mu}_k (1 - \bar{\mu}_k)},$$

o_k = number of observed 'successes' in group k , n_k = size of the group, $\bar{\mu}_k$ = the mean number of the estimated probabilities of success, $\bar{\mu}_k = \sum_{i \in G_k} \hat{\mu}_i / n_k$, where G_k is the k th group, and where $\mu_i = \Pr(y_i = 1, I_i = 1, R_i = 1 | x_i)$

The population mean of the constraining variables \mathbf{c} need to be known. We use proxy variables for the model variables \mathbf{y}, \mathbf{x} .

A limited study of: (1) Best choice of variables for which the auxiliary variables are proxy, (2) how close should the auxiliary variables be to the variables they are proxy for, and (3) how many auxiliary variables to choose.

The correlation with the target model's variables is more important than the 'noise'.

Even just two auxiliary variables may be enough.

$$\mathbf{c}_i = (1, x_i, y_i, x_i y_i, x_i^2, x_i^2 y_i)' + \varepsilon_i, \quad \varepsilon_i \sim N(0, \sigma_c^2 \mathbf{I}_6)$$
